Abstract. This paper studies the problem of reconstructing binary matrices that are only accessible through few evaluations of their discrete X-rays. Such question is prominently motivated by the demand in material science for developing a tool for the reconstruction of crystalline structures from their images obtained by high-resolution transmission electron microscopy. Various approaches have been suggested for solving the general problem of reconstructing binary matrices that are given by their discrete X-rays in a number of directions, but more work have to be done to handle the ill-posedness of the problem. We can tackle this ill-posedness by limiting the set of possible solutions, by using appropriate a priori information, to only those which are reasonably typical of the class of matrices which contains the unknown matrix that we wish to reconstruct. Mathematically, this information is modelled in terms of a class of binary matrices to which the solution must belong. Several papers study the problem on classes of binary matrices on which some connectivity and convexity constraints are imposed.

We study the reconstruction problem on some new classes consisting of binary matrices with periodicity properties, and we propose a polynomial-time algorithm for reconstructing these binary matrices from their orthogonal discrete X-rays.

keywords: combinatorial problem, discrete tomography, binary matrix, polyomino, periodic constraint, discrete X-rays.

1 Introduction

The present paper studies the possibility of determining the geometrical aspects of a discrete physical structure whose interior is accessible only through a small number of measurements of the atoms lying along a fixed set of directions. This is the central theme of *Discrete Tomography* and the principal motivation of this study is in the attempt to reconstruct three-dimensional crystals from two-dimensional images taken by a transmission electron microscope. The quantitative analysis of these images can be used to determine the number of atoms in atomic lines in certain directions [22,27]. The question is to deduce the local

atomic structure of the crystal from the atomic line count data. The goal is to use the reconstruction technique for quality control in VLSI (Very Large Scale Integration) technology. Before showing the results of this paper, we give a brief survey of the relevant contributions in Discrete Tomography.

Clearly, the best known and most important part of the general area of tomography is *Computerized Tomography*, an invaluable tool in medical diagnosis and many other areas including biology, chemistry and material science. Computerized Tomography is the process of obtaining the density distribution within a physical structure from multiple X-rays. More formally, we attempt to reconstruct a density function $f(x)$ for x in $\mathbb{R}^2$ or $\mathbb{R}^3$ from knowledge of its line integral $X_f(L) = \int_L f(x)dx$ for lines L through the space. This line integral is the *X-ray* of $f(x)$ along L . The mapping $f \rightarrow X_f$ is known as the *Radon transform*. The mathematics of Computerized Tomography is quite well understood. Appropriate quadratures [28,29] of the Radon inversion formula are used, with concepts from calculus and continuous mathematics playing the main role.

Usually, the physical structure has a very big variety of density values, and so a large number of X-rays are necessary to ensure the accurate reconstruction of their distribution. In some cases the structure that we want to reconstruct has only a small number of possible values. For example, a large number of objects encountered in industrial computerized tomography (for the purpose of non-destructive testing or reverse engineering) [9] are made of a single homogeneous material. In many of these applications there are strong technical reasons why only a few X-rays of the structure can be physically determined. *Discrete Tomography* is the area of Computerized Tomography in which these special cases are studied. The name Discrete Tomography is due to Larry Shepp, who organized the first meeting devoted to the topics in 1994.

An example of such a case is the above-mentioned problem of determining local atomic structure of a crystal from the atomic line count data. In a simple but highly relevant model suggested by Peter Schwander and Larry Shepp the possible atom locations in a unit cell of a crystal are defined on the integer lattice $\mathbb{Z}^3$, while the electron beams are modeled as lines parallel to a given direction. The presence of an atom at a specific location corresponds to a pixel value one at the location; the absence of an atom corresponds to a pixel value zero. The number of atoms along certain lines through the crystal (i.e., the sum of pixel values along those lines) define the *discrete X-rays* of the atomic structure with respect to the family of lines involved. Since in practice, one degree of freedom for moving the imaging device is used to control the position of the crystal, the view directions for which data are provided lie all in the same plane. This means that the 3D-problem leads itself to a 2D-slice-by-slice reconstruction. Therefore, the crystal is represented by a binary matrix and its discrete X-ray along a direction u is an integral vector giving the sum of its elements on each line parallel to u (see Fig. 1).

Measurements are usually only available along two, three or four directions, which is much less than what is typically used in Computerized Tomography (a few hundred). In fact, the electron microscope makes measurements at the atomic

Fig. 1. A subset F of $\mathbb{Z}^2$ with the corresponding binary matrix. $X_{(1,0)}F$, $X_{(0,1)}F$ and $X_{(1,1)}F$ are the discrete X-rays in the directions $(1, 0)$, $(0, 1)$ and $(1, 1)$.

level and uses high energy (and so deeply penetrating) rays which can corrupt the crystal itself. So, it can take only two, three or four images of the crystal before the energy of the radiations destroys it, or at least changes permanently its atomical configuration so that the subsequent radiations will see something different from the original one.

Now, the problem is to invert the *discrete Radon transform*, i.e., to reconstruct the binary matrix from this small set of discrete X-rays. More precisely, the basic question is to determine, given a set of directions $u_1, \dots, u_k$ and a set of integral vectors $X_1, \dots, X_k$, whether there exists a binary matrix F whose discrete X-rays along $u_1, \dots, u_k$ are $X_1, \dots, X_k$. The general methods of Computerized Tomography cannot be used effectively if the number of X-rays is so small, and they seems unlikely to work in practice.

Discrete Tomography has its own mathematical theory mostly based on discrete mathematics. It has some strong connection with combinatorics and geometry. We wish to point out that the mathematical techniques developed in Discrete Tomography have applications in other fields such as: image processing [30], statistical data security [21], biplane angiography [25], graph theory [2] and so on. As a survey of the state of the art of Discrete Tomography we can suggest the book [20].

Interestingly, mathematicians have been concerned with abstract formulations of these problems before the emergence of the practical applications. Many problems of Discrete Tomography were first discussed as combinatorial problems during the late 1950s and early 1960s. In 1957 Ryser [26] and Gale [13] gave a necessary and sufficient condition for a pair of vectors being the discrete X-rays of a binary matrix along horizontal and vertical directions. The discrete X-rays in horizontal and vertical directions are equal to *row* and *column sums* of the matrix. They gave an exact combinatorial characterization of the row and column sums that correspond to a binary matrix, and they derived a fast $O(nm)$ time algorithm for reconstructing a matrix, where n and m denote its sizes. We

refer the reader to an excellent survey on the binary matrices with given row and column sums by Brualdi [8].

The space of solutions of the reconstruction problem, however, is really huge and in general quite impossible to control. A good idea may seem to start increasing the number of X-rays one by one in order to decrease the number of solutions. Unfortunately, the reconstruction problem becomes intractable when the number of X-rays is greater than two, as proved in [14]. This means that (unless $P = NP$) exact reconstructions require, in general, an exponential amount of time. In polynomial time only approximate solutions can be expected. In this context, an approximate solution is close to the optimal one if its discrete X-rays in the set of prescribed directions are close to those of the original set. Various approaches have been suggested for solving the problem [12,31,32]. Recently, an interesting method [18] for finding an approximate solutions has been proposed. Even though the reconstruction problem is intractable, some simple algorithms proposed in [18] have good worst-case bounds and they perform even better in computational practice.

Unluckily, this is not still enough. During the last meeting devoted to Discrete Tomography, Gabor T. Herman [19] and Peter Gritzmann [17] stress the fact that various approaches have been suggested for solving the general problem of reconstructing binary matrices that are given by their discrete X-rays in a small number of directions, but more work has to be done to handle the ill-posedness of the problem. In fact, the relevant measure for the quality of a solution of the problem would be its deviation from the original matrix. Hence in order to establish this deviation we would have to know the real binary matrix. However, the goal is to find this unknown original binary matrix so we can only consider measures for the quality of a solution based on the given input discrete X-rays. We have a good solution in this sense if its discrete X-rays in the prescribed directions are close to those of the original matrix. Unfortunately, if the input data do not uniquely determine the matrix even a solution having the given discrete X-rays may be very different from the unknown original matrix. It is shown in [1] that extremely small changes in the data may lead to entirely different solutions. Consequently, the problem is ill-posed, and in a strict mathematical setting we are not able to solve this problem and get the correct solution.

In most practical application we have some a priori information about the images that have to be reconstructed. So, we can tackle the algorithmic challenges induced by the ill-posedness by limiting the class of possible solutions using appropriate prior information. The reconstruction algorithms can take advantage of this further information to reconstruct the binary images.

A first approach is given in [24], where it is posed the hypothesis that the binary matrix is a typical member of a class of binary matrices having a certain Gibbs distribution. Then, by using this information we can limit the class of possible solutions to only those which are close to the given unknown binary matrix. A modified Metropolis algorithm based on the known Gibbs prior pro-

vides a good tool to move the reconstruction process toward the correct solution when the discrete X-rays by themselves are not sufficient to find such solution.

A second approach modelled a priori information in terms of a subclass of binary images to which the solution must belong. Several papers study the problem on classes of binary matrices having convexity or connectivity properties. By using these geometric properties we reduce the class of possible solutions. For instance, there is a uniqueness result [15] for the subclass of *convex binary matrices* (i.e., finite subsets F of $\mathbb{Z}^n$ such that $F = \mathbb{Z}^n \cap \text{conv}(F)$). It is proved that a convex binary matrix is uniquely determined by its discrete X-rays in certain prescribed sets of four directions or in any seven non-parallel coplanar directions. Moreover, there are efficient algorithms for reconstructing binary matrices of these subclasses defined by convexity or connectivity properties. For example, there are polynomial time algorithms to reconstruct *hv-convex polyominoes* [4,11,5] (i.e., two-dimensional binary matrices which are 4-connected and convex in the horizontal and vertical directions) and convex binary matrices [6,7] from their discrete X-rays. At the moment, several researchers are studying the following stability question: given a binary matrix having some connectivity and convexity properties and its discrete X-rays along three or four directions, is it possible that small changes in the data lead to “dramatic” change in the binary matrix ?

In this paper, we take the second approach into consideration, and we propose some new subclasses consisting of binary matrices with periodicity properties. The periodicity is a natural constraint and it has not yet been studied in Discrete Tomography. We provide a polynomial-time algorithm for reconstructing $(p, 1)$ -periodical binary matrices from their discrete X-rays in the horizontal and vertical directions (i.e., row and column sums). The basic idea of the algorithm is to determine a polynomial transformation of our reconstruction problem to 2-Satisfiability problem which can be solved in linear time [3]. A similar approach has been described in [4,10].

We wish to point out that this paper is only an initial approach to the problem of reconstructing binary matrices having periodicity properties from a small number of discrete X-rays. There are many open problems on these classes of binary matrices of interest to researchers in Discrete Tomography and related fields: the problem of uniqueness, the problem of reconstruction from three or more X-rays, the problem of reconstructing binary matrices having convexity and periodicity properties, and so on.

2 Definitions and preliminaries

Notations. Let $A^{m \times n}$ be a binary matrix, $r_i = \sum_{j=1}^n a_{i,j}$ and $c_j = \sum_{i=1}^m a_{i,j}$, for each $1 \leq i \leq m$ and $1 \leq j \leq n$. We define $R = (r_1, \dots, r_m)$ and $C = (c_1, \dots, c_n)$ as the vectors of *row* and *column sums* of A , respectively. The enumeration of the rows and columns of A starts with row 1 and column 1 which intersect in the upper left position of A . A realization of (R, C) is a matrix B whose row and column sums are R and C .

A binary matrix $A^{m \times n}$ is said to be (p, q) -periodical if $a_{i,j} = 1$ implies that

$$a_{i+p,j+q} = 1 \text{ if } 1 \leq i+p \leq m \text{ and } 1 \leq j+q \leq n,$$

$$a_{i-p,j-q} = 1 \text{ if } 1 \leq i-p \leq m \text{ and } 1 \leq j-q \leq n.$$

Such a matrix is said to have *period* (p, q) .

For any given couple (x, y) such that $a_{x,y} = 1$ we define the set P of propagation of the value in position (x, y) in direction (p, q) , $P = \{(x + kp, y + kq) | 1 \leq x + kp \leq m, 1 \leq y + kq \leq n, k \in \mathbb{Z}\}$. Such set is called a *line*. Each line has a *starting point*, which is its leftmost point, and an *ending point*, which is its rightmost point. We say that a line starts on column j and ends on column j' when its starting and ending points are on column j and j' , respectively.

The notion of *box* is a crucial part for our work. Let A be a (p, q) -periodical matrix. From the periodicity it follows that if there exists an index $1 \leq i \leq m$ such that

$r_i = r_{i+p} + k$, then the positions on row i , from column $n - q + 1$ to column n , contain at least k elements equal to 1. Such positions form a box at the end of row i and will be addressed to as *right box* (rt);

$r_i + k = r_{i+p}$, then on row $i + p$, from column 1 to column q we have k elements equal to 1. Such positions form a box at the beginning of the row i and will be addressed to as *left box* (lt);

We define the upper and lower boxes (up and lw respectively) on columns in the same way (see Fig. 2), if there exists an index $1 \leq j \leq n$ such that

$c_j = c_{j+q} + k$ then the positions on column j , from row $m - p + 1$ to row m , contain at least k elements equal to 1. Such positions form a box at the end of column j and will be addressed to as lower box (lw);

$c_j + k = c_{j+q}$ then the positions on column $j + q$, from row 1 to row p , contain at least k elements equal to 1. Such positions form a box at the beginning of column j and will be addressed to as upper box (up);

Fig. 2. A $(2, 1)$ -periodical binary matrix with upper (up), lower (lw), right (rt) and left (lt) boxes.

Definitions of polyominoes. A *polyomino* P is a finite union of elementary cells of the lattice $\mathbb{Z} \times \mathbb{Z}$ whose interior is connected. This means that, for any pair of cells of P there exists a lattice path in P connecting them (see Fig. 3(a)). A lattice path is a path made up of horizontal and vertical unitary steps. These sets are well-known combinatorial objects [16] and are called *digital 4-connected sets* in discrete geometry and computer vision. We point out that a polyomino can be easily represented by a binary matrix.

A polyomino is said to be *v-convex* [*h-convex*], when its intersection with any vertical [horizontal] line is convex. A polyomino is *hv-convex* or *simply convex* when it is both horizontal and vertical convex. A *parallelogram polyomino* is a polyomino whose boundary consists of two non intersecting paths (except at their origin and extremity) having only north or west steps. Fig. 3 shows polyominoes having the above-mentioned geometric properties.

Fig. 3. a) A polyomino. b) A *h-convex* polyomino. c) A *hv-convex* polyomino. d) A parallelogram polyomino.

3 Periodicity (1, 1)

Let A be a (1,1)-periodical matrix.

By definition of boxes for $p = 1$ and $q = 1$ the boxes are reduced to only one cell and the integer k of the definition takes only the values 0 or 1. If there exists an index $1 \leq i \leq m$ or $1 \leq j \leq n$ such that

$$\begin{aligned}
 r_i &= r_{i+1} + 1 \text{ then } a_{i,n} = 1. \\
 r_i + 1 &= r_{i+1} \text{ then } a_{i+1,1} = 1. \\
 c_j &= c_{j+1} + 1 \text{ then } a_{m,j} = 1. \\
 c_j + 1 &= c_{j+1} \text{ then } a_{1,j+1} = 1.
 \end{aligned}$$

A preprocessing part uses the previous box properties to extract the fixed part (called F) of the reconstruction matrix. The following algorithm performed on a given pair of vectors (R, C) gives, if a solution exists, the fixed part (namely the matrix F) and a pair of vectors (R', C') of the mobile part.

Propagation (x, y, F, ℓ)

$P = \{(x+k, y+k) | 1 \leq x+k \leq m, 1 \leq y+k \leq n, k \in \mathbb{Z}\};$
For all $(i, j) \in P$ **do** $F_{i,j} = 1, r_i^{(\ell+1)} = r_i^{(\ell)} - 1, c_j^{(\ell+1)} = c_j^{(\ell)} - 1;$

The main program finds the fixed 1's by considering the differences between the values of the pair of vectors. For each fixed 1, the procedure Propagation fills by periodicity (1, 1) the matrix F and decreases the row and column sum of the current matrix.

At the end of the preprocessing part both row and column vectors are homogeneous ($r'_i = \rho$ for all $1 \leq i \leq m$ and $c'_j = \gamma$ for all $1 \leq j \leq n$).

Now, either (R', C') are zero vectors and then the solution is unique and equal to F , or we perform a reconstruction from homogeneous X-rays with periodicity (1, 1).

Since the vectors are homogeneous we can extend the periodicity on a torus. Indeed, suppose that $r'_i = r'_{i+1}$ with $r'_i = \sum_{j=1}^n a'_{i,j}$ and $r'_{i+1} = \sum_{j=1}^n a'_{i+1,j}$. By periodicity $a'_{i,j} = a'_{i+1,j+1}$, for $j = 1, \dots, n-1$, implies that $a'_{i,n} = a'_{i+1,1}$, for $i = 1, \dots, m-1$. In other terms the values of the matrix A' are mapped on a cylinder. The same argument in column proves that the values of the matrix A' are mapped on a torus. That is if $a'_{i,j} = 1$ then $a'_{i+1 \bmod m, j+1 \bmod n} = 1$ and $a'_{i-1 \bmod m, j-1 \bmod n} = 1$.

So, a solution is formed by loops, namely a beginning in (i, j) with $a'_{i,j} = 1$ and a propagation by periodicity (1, 1) until the position (i, j) . All the loops have the same length. As the vectors are homogeneous, we can compute the number of loops. Using this strong condition and the algorithm of Ryser [26] in the first row in order to place the loops, we can reconstruct easily a solution in $O(mn)$ time.

Another remark is the arithmetical nature of the stability of the solution. We can prove that if m and n are relatively prime then there is only one solution. Indeed in this case, to perform a reconstruction of a binary matrix with homogeneous vector, we have only one loop felling the whole matrix and then either the matrix A' is full of 1's or full of 0's and nothing between because of the toric conditions.

Proposition 1. *Let $R \in \mathbb{N}^m$ and $C \in \mathbb{N}^n$. If $\gcd(n, m) = 1$, then there is at most a (1, 1)-periodical matrix having row and column sums equal to (R, C) .*

For example, if we perform a reconstruction with a matrix with m rows and $m+1$ columns and periodicity (1, 1) then the solution is unique if it exists.

Example 1. For $R = (2, 2, 1, 2), C = (2, 1, 2, 2)$, the algorithm gives the matrix

$$F = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}$$

and the vectors $R = (1, 1, 1, 1), C = (1, 1, 1, 1)$.

We can reconstruct two solutions for $R = (2, 2, 1, 2), C = (2, 1, 2, 2)$:

$$\begin{aligned}
& \begin{matrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \end{matrix} \\
A'_1 = & \\
\text{and} & \\
& \begin{matrix} 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \end{matrix} \\
A'_2 = &
\end{aligned}$$

For $R = (1, 2, 2, 2), C = (2, 1, 2, 1, 1)$, the algorithm gives a fixed part and $R = (0, 0, 0, 0), C = (0, 0, 0, 0, 0)$, then the solution is unique.

$$\begin{aligned}
& \begin{matrix} 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 \end{matrix} \\
F = &
\end{aligned}$$

4 Periodicity $(p, 1)$ with $1 < p < m$

Let A be a matrix with periodicity $(p, 1)$.

The preprocessing part uses only the row sums in order to find the fixed part of the reconstruction. In fact, by definition of boxes for $q = 1$ the horizontal boxes are reduced to only one cell and the integer k of the definition takes only the values 0 or 1. If there exists an index $1 \leq i \leq m$ such that

$$\begin{aligned}
r_i &= r_{i+p} + 1 \text{ then } a_{i,n} = 1. \\
r_i + 1 &= r_{i+1} \text{ then } a_{i+p,1} = 1.
\end{aligned}$$

A preprocessing part uses the previous box properties to extract the fixed part (called F) of the reconstruction matrix. The following algorithm performed on a given pair of vectors (R, C) gives, if a solution exists, the fixed part (namely the matrix F) and a pair of (R', C') of the mobile part.

Algorithm 2

Input: A pair of integral vectors (R, C) ;

Output: If $PB = 0$, then it gives Matrix F and couple of integral vector (R', C') ;
or If $PB = 1$ Failure in the reconstruction;

Initialisation: $\ell := 0, PB := 0, R^{(\ell)} := R, C^{(\ell)} := C, F = 0^{m \times n}$;

while $R^{(\ell)}$ is positive non homogeneous vector and $PB = 0$ **do**

$R^{(\ell+1)} := R^{(\ell)}, C^{(\ell+1)} := C^{(\ell)}$;

determine first index s.t. $r_i^{(\ell)} \neq r_{i+p}^{(\ell)}$;

if $r_i^{(\ell)} = r_{i+p}^{(\ell)} + 1$ **then** $x := i, y := n$, **Propagation** (x, y, F, ℓ) ;

else if $r_i^{(\ell)} + 1 = r_{i+p}^{(\ell)}$ **then** $x := i + p, y := 1$, **Propagation** (x, y, F, ℓ)

else $PB := 1$;

$\ell := \ell + 1;$
end while;

Propagation(x, y, F, ℓ)

$P = \{(x + kp, y + k) | 1 \leq x + kp \leq m, 1 \leq y + k \leq n, k \in \mathbb{Z}\};$
For all $(i, j) \in P$ **do** $F_{i,j} = 1, r_i^{(\ell+1)} = r_i^{(\ell)} - 1, c_j^{(\ell+1)} = c_j^{(\ell)} - 1;$

The main program finds the fixed 1's by considering the differences between the values of the row sums. For each fixed 1, the procedure Propagation fills by periodicity $(p, 1)$ the matrix F and decreases the row and column sum of the current matrix.

At the end of the preprocessing part the row vector sum R' of A' has the same value on indices in arithmetical progression of rank p : $r'_i = r'_{i+p} = r'_{i+2p} \cdots = r'_{i+(\ell-1)p}$ where $\ell = L$ or $L + 1$. This set of element of the row sums R' of A' is called *line* of R' . The minimum length of each line of R' is $L = \lfloor \frac{m}{p} \rfloor$. The number of lines of length $L + 1$ and L of R' is $n_{L+1} = m \bmod p$ and $n_L = p - n_{L+1}$, respectively.

Example 2. If $(p, 1) = (2, 1)$, and $R = (2, 3, 2, 4, 3, 4, 2), C = (3, 4, 3, 3, 4, 2, 1)$, the algorithm gives the matrix

$$F = \begin{pmatrix} 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

and the new vectors are $R' = (1, 3, 1, 3, 1, 3, 1), C' = (1, 2, 3, 3, 3, 1, 0)$. Since $m = 7$ and $p = 2$, we have that $L = 3, n_L = 1, n_{L+1} = 1$. So, $R' = (1, 3, 1, 3, 1, 3, 1)$ contains a line of length $L = 3$ and a line of length $L + 1 = 4$. Since the lines of length $L = 3$ and $L + 1$ are $(*, 3, *, 3, *, 3, *)$ and $(1, *, 1, *, 1, *, 1)$, respectively, we have that matrix A' contains a line of length three lines of length $L = 3$ starting from the second row and $L + 1 = 4$ starting from the first row.

Now, we prove now the values of A' are mapped on a cylinder. We have $r'_i = r'_{i+p}$ with $r'_i = \sum_{j=1}^n a'_{i,j}$ and $r'_{i+p} = \sum_{j=1}^n a'_{i+p,j}$. From the periodicity $a'_{i,j} = a'_{i+p,j+1}$, for $j = 1, \dots, n - 1$, it follows that $a'_{i+p,1} = a'_{i,n}$, for $i = 1, \dots, m - p$. In other terms the values of the matrix A' are mapped on a cylinder.

Thus a 1 on the first p rows (at position $(x, y), 1 \leq x \leq p, 1 \leq y \leq n$) can be extended by periodicity on the matrix A' by 1's in positions $(x + kp, y + k \bmod n)$ with $k = 0, \dots, \ell - 1$ where $\ell = L$ or $L + 1$. The matrix A' is in particular composed on a cylinder of lines in direction $(p, 1)$ of length L or $L + 1$. In addition to that the number of lines of length $L + 1$ is exactly $n_{L+1} = m \bmod p$ and the number of lines of length L is $n_L = p - n_{L+1}$.

4.1 A reduction to the problem of reconstructing a special class of h -convex binary matrices lying on a cylinder

Let A' be a solution for a given (R', C') with $r'_i = r'_{i+p} = r'_{i+2p} \cdots = r'_{i+(\ell-1)p}$ where $\ell = L$ or $L+1$. We now perform a reduction of reconstruction of $(p, 1)$ -periodical matrix A' on a cylinder to a reconstruction of a special h -convex matrix A'' on a cylinder.

By the previous construction, matrix A' is formed by lines $(x + kp, j + k \bmod n)$ with $k = 0, \dots, \ell - 1$ where $\ell = L$ or $L+1$. The starting points of the lines is the set of position $S = \{(x, y) | 1 \leq x \leq p, 1 \leq y \leq n, a'_{x,y} = 1\}$.

S is ordered by: $(x, y) \leq (x', y')$ if and only if $x \geq x'$ and $y \leq y'$ (i.e., we proceed from bottom to up and from left to right).

Let S' be the set S with an extra index of the rank in the previous order. Each element of S' is a triple (x, y, o) , where (x, y) is an element of S and o the rank in the order. Now, we can describe the reduction.

Reduction. Let $(x, y, o) \in S'$. The point (x, y) is the starting point of a line of matrix A' having length L or $L+1$. This line gives a horizontal bar of 1's begins in position $(o, y + r \bmod n)$ with $r = 1, \dots, \ell$ where $\ell = L$ if $x > n_{L+1}$ or $\ell = L+1$ if $x \leq n_{L+1}$. The set of these horizontal bars gives the h -convex matrix A'' .

Notice that, this transformation makes the column sum of A'' equal to the column sum of A' . In Section 4.3, we will show the inverse reduction that provides A' from A'' .

Example 3. Let us take the following matrix A' with periodicity $(2, 1)$ and $R' = (3, 2, 3, 2, 3)$ and $C' = (3, 3, 2, 1, 2, 2)$ into consideration.

$$A' = \begin{pmatrix} 1 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 0 \\ 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 & 1 & 0 \end{pmatrix}$$

Since $m = 5$ and $p = 2$, we have that $L = 2$, $n_{L+1} = 1$. The matrix A' is composed of three lines of length $L+1 = 3$ and two lines of length $L = 2$. The starting points in the first two rows (the two first indices are the position in the matrix A' and the last index is the rank in the order) are:

$$S' = \{(2, 1, 1), (1, 1, 2), (1, 3, 3), (2, 5, 4), (1, 6, 5)\}.$$

The transformation gives the following h -convex matrix A'' mapped on a cylinder with three bars of length three and two bars of length two.

$$A'' = \begin{pmatrix} 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 0 & 0 & 1 \end{pmatrix}$$

The column sums of A'' are equal to $C' = (3, 3, 2, 1, 2, 2)$.

We point out that the order on the starting points adds the following constraints:

Condition 1. On each column of A'' can start at most n_L bars of length L and at most n_{L+1} bars of length $L + 1$. Moreover, by proceeding from up to down on the column at first we find the bars of the length L and then the bars of the length $L + 1$ (see Fig. 4).

Fig. 4. A column of a binary matrix satisfying condition 1.

We denote the class of h -convex binary matrices lying on a cylinder and satisfying condition 1 by $\mathcal{HC}(n_L, n_{L+1})$.

By this property, the matrix A'' consists of four disjoint zones B, C, E and P whose boundaries are three paths having only north or west steps, and $a''(i, j) = 1$ for $(i, j) \in C \cup P$ and $a''(i, j) = 0$ for $(i, j) \in B \cup E$ (see Fig. 5 and the matrix A'' of the previous example). Notice that, the matrices of the class $\mathcal{HC}(n_L, n_{L+1})$ are set of parallelogram polyominoes lying on a cylinder.

From the reduction it follows that the problem of reconstructing a $(p, 1)$ -periodical binary matrix A' having row and column sums (R', C') (output of Algorithm 1) is equivalent to the problem of reconstructing a binary matrix A'' of $\mathcal{HP}(n_L, n_{L+1})$ having column sums C' , m rows of length L and $L + 1$. We denote this reconstruction problem on the cylinder by **RHC** problem.

In the following subsection, we determine a polynomial transformation of **RHC** problem to 2-Satisfiability problem (2-SAT).

4.2 A reduction to the 2-SAT problem

Given an instance I of **RHC** problem, we want to build a 2-SAT formula Ω (a formula in conjunctive normal form, where each clause has at most two literals) whose satisfiability is linked to the existence of a solution for I in such a way: if Ω is satisfiable, then we are able to reconstruct a solution for I in P-time and, vice versa, each solution of I gives an evaluation of the variables satisfying Ω in P-time. We will do not show the proofs of the lemmas of this section for brevity's sake. Let I be an instance of **RHC** problem; that is:

- two integers n_L, n_{L+1} ;
- a couple (L, C) , where L and $L+1$ are the only possible values of the row sums of a binary matrix A'' of $\mathcal{HC}(n_L, n_{L+1})$, solution of I , and $C = (c_1, \dots, c_n)$ is its column sums.
- an integer m which denotes the number of rows of A'' .

The formula Ω that we want to construct is the conjunction of three 2-SAT formulas: Ω_1 which encodes the geometrical constraints of A'' , Ω_2 which gives the consistency of A'' with the couple (L, C) and, finally, Ω_3 which imposes the constraints of condition 1 on each column of A'' . The variables of the formula Ω belong to the union of the four disjoint sets of variables:

$$\mathcal{B} = \{b(i, j) : 1 \leq i \leq m, 1 \leq j \leq n\}, \quad \mathcal{C} = \{c(i, j) : 1 \leq i \leq m, 1 \leq j \leq n\},$$

$$\mathcal{P} = \{p(i, j) : 1 \leq i \leq m, 1 \leq j \leq n\}, \quad \mathcal{E} = \{e(i, j) : 1 \leq i \leq m, 1 \leq j \leq n\}.$$

We use the variables of the set $\mathcal{X}_i$, with $\mathcal{X}_i \in \{\mathcal{B}, \mathcal{C}, \mathcal{P}, \mathcal{E}\}$, to represent the four disjoint zones B, C, P, E inside A .

Coding in Ω_1 the geometrical constraints of A'' . Formula Ω_1 is the conjunction of the following sets of clauses:

$$Corners = \bigwedge_{i,j} \left\{ \begin{array}{l} (x(i, j) \Rightarrow x(i-1, j)) \wedge (x(i, j) \Rightarrow x(i, j+1)) \text{ for } x \in \mathcal{C} \cup \mathcal{E} \\ (x(i, j) \Rightarrow x(i+1, j)) \wedge (x(i, j) \Rightarrow x(i, j-1)) \text{ for } x \in \mathcal{B} \cup \mathcal{P} \end{array} \right\}$$

$$Disj = \bigwedge_{i,j} \{ (b(i, j) \Rightarrow \bar{c}(i, j)) \wedge (p(i, j) \Rightarrow b(i, j)) \wedge (e(i, j) \Rightarrow c(i, j)) \}$$

$$Compl = \bigwedge_{i,j} \{ \bar{b}(i, j) \Rightarrow c(i, j) \}$$

$$Anch = \{ \bar{e}(1, L) \wedge \bar{p}(m, L+1) \wedge p(r, 1) \}$$

with $1 < r \leq m$.

Definition 1. Let V_1 be an evaluation of the variables in $\mathcal{B}, \mathcal{C}, \mathcal{P}, \mathcal{E}$ which satisfies Ω_1 . We define the binary matrix A'' of size $m \times n$ as follows:

$$\begin{aligned} (c(i, j) = 1 \wedge e(i, j) = 0) &\Rightarrow a''(i, j) = 1, & p(i, j) = 1 &\Rightarrow a''(i, j) = 1, \\ (b(i, j) = 1 \wedge p(i, j) = 0) &\Rightarrow a''(i, j) = 0, & e(i, j) = 0 &\Rightarrow a''(i, j) = 0. \end{aligned}$$

It is immediate to check that A'' is well defined.

The matrix A'' contains the four zones B, C, E and P of A such that: $(i, j) \in X$, with $X \in \{B, C, E, P\}$ if and only if $x(i, j) = 1$ (see Fig. 5). From *Corners*, *Disj*, *Compl* and *Anch* we deduce the following properties these four zones:

- Lemma 1.** i) $\{B, C\}$ is a partition of A'' , $P \subseteq B$ and $E \subseteq C$;
ii) the boundary of zones B, C, E and P is made up of three paths having only north or west steps;
iii) there does not exist a column of A'' containing both points of P and points of E .

Fig. 5. The matrix A'' and the four zones B, C, E and P of A defined by the formulas *Corners*, *Disj*, *Compl* and *Anch*.

Coding in Ω_2 the bound of the row and column sums of A'' . The formula Ω_2 is the conjunction of the following sets of clauses:

$$\begin{aligned}
LBC &= \bigwedge_{i,j} \left\{ \begin{array}{l} \text{if } j > L, e(i, j) \Rightarrow \bar{b}(i + c_j, j) \\ \text{if } j \leq L, b(i, j) \Rightarrow p(i + m - c_j, j) \end{array} \right\} \\
UBC &= \bigwedge_{i,j} \left\{ \begin{array}{l} \text{if } j > L, \bar{e}(i, j) \Rightarrow b(i + c_j, j) \\ \text{if } j \leq L, \bar{b}(i, j) \Rightarrow \bar{p}(i + m - c_j, j) \end{array} \right\} \\
UBR &= \bigwedge_{i,j} \left\{ \begin{array}{l} \text{if } i < r, \bar{b}(i, j) \Rightarrow e(i, j + L + 1) \\ \text{if } i \geq r, p(i, j) \Rightarrow \bar{c}(i, j + n - L - 1) \end{array} \right\} \\
LBR &= \bigwedge_{i,j} \left\{ \begin{array}{l} \text{if } i < r, b(i, j) \Rightarrow \bar{e}(i, j + L) \\ \text{if } i \geq r, \bar{p}(i, j) \Rightarrow c(i, j + n - L) \end{array} \right\}.
\end{aligned}$$

The formulas LBC and UBC give a lower and an upper bound for the column sums of A . The formula LBR express that the row sums are greater than L . Finally, the formula UBR express that the row sums are smaller than $L + 1$. More precisely,

Lemma 2. *Let A'' be the binary matrix defined by means of the valuation V_2 which satisfies $\Omega_1 \wedge \Omega_2$ as in Definition 1. We have that:*

- i) the column sums of A'' are equal to $C = (c_1, \dots, c_n)$;*
- ii) each row sum of A'' has value L or $L + 1$ (see Figure 5).*

Fig. 6. The matrix A'' with the bounds on row and column sums.

Coding in Ω_3 the maximum number of bars of length L and $L + 1$ starting on each column of A'' . The formula Ω_3 is the conjunction of the following sets of clauses:

$$\begin{aligned}
 BB_L &= \bigwedge_{i,j} \left\{ \begin{array}{l} \text{if } i \leq m - c_n, \quad e(i, j) \Rightarrow \bar{b}(i - n_{L+1}, j - L - 1) \\ \text{if } m - c_n < i < r, \quad r - (m - c_n) - 1 > n_{L+1} \Rightarrow \bar{b}(m - c_n + 1, n - L) \\ \text{if } (i \geq r \wedge j \leq L), \quad \bar{p}(i, j) \Rightarrow \bar{b}(i - n_{L+1}, j + n - L - 1) \end{array} \right\} \\
 BB_{L+1} &= \bigwedge_{i,j} \left\{ \begin{array}{l} \text{if } i \leq n - c_n, \quad c(i, j) \Rightarrow e(i - n_L, j + L) \\ \text{if } n - c_n < i < r, \quad r - (m - c_n) - 1 > z_1 \Rightarrow \bar{c}(m - c_n + n_L + 1, n - L) \\ \text{if } i \geq r, \quad c(i, j) \Rightarrow \bar{p}(i - n_L, j + L - n) \end{array} \right\}
 \end{aligned}$$

Lemma 3. *Let A'' be the binary matrix defined by means of the valuation V_3 which satisfies $\Omega_1 \wedge \Omega_2 \wedge \Omega_3$ as in Definition 1. We have that:*

- i) on each column of A'' can start at most n_L bars of length L ,*
- ii) on each column of A'' can start at most n_{L+1} bars of length $L + 1$.*

By Lemmas 1 and 3, matrix $A'' \in \mathcal{HP}(n_L, n_{L+1})$. By Lemma 2, matrix A'' satisfies the tomographic constraints. Therefore:

Theorem 1. $\Omega_1 \wedge \Omega_2 \wedge \Omega_3$ is satisfiable if and only if there is a binary matrix A'' of $\mathcal{HP}(n_L, n_{L+1})$ having column sum C' , m rows of length L and $L + 1$.

Since $\Omega_1 \wedge \Omega_2 \wedge \Omega_3$ is a boolean formula in conjunctive normal form with at most two literals in each clause, by Theorem 1 we have a polynomial time transformation of **HRC** problem to 2-SAT problem which can be solved in linear time [3].

4.3 Final Step

By performing the previous reduction and an algorithm for solving 2-SAT problem [3], we obtain a matrix A'' of $\mathcal{HP}(n_L, n_{L+1})$ having column sums C' , m rows of length L and $L + 1$, where $n_{L+1} = m \bmod p$ and $n_L = p - n_{L+1}$. Now, for determining a $(p, 1)$ -periodical matrix A' having row and column sums equal to (R', C') , we have to perform the inverse of the reduction defined in Section 4.1. We point out that (R', C') is the output of Algorithm 2. This inverse reduction should provides A' from A'' . The following algorithm describes this inverse reduction.

Algorithm 3

Input: the matrix A'' whose column sums is vector C' , and vector R'
which is homogeneous with respect to p (R' is the output of Algorithm 2);
Output: the matrix A' having row and column sums (R', C') ;
Step 1: determine the two vectors $C^{(1)} = (c_1^{(1)}, \dots, c_n^{(1)})$, $C^{(2)} = (c_1^{(2)}, \dots, c_n^{(2)})$
such that $c_i^{(1)}$ and $c_i^{(2)}$ are the number of bars starting from the i -th
column of A'' having length L and $L + 1$, respectively, ;
Step 2: construct the matrix A' of size $m \times n$ in such a way:
if $1 \leq i \leq (m - p)$ and $1 \leq j \leq n$, we set $a'(i, j) = 0$;
if $(m - p + 1) \leq i \leq (m - p + n_{L+1})$ and $1 \leq j \leq n$, **then** perform Ryser's
reconstruction algorithm on the row and column vectors:
 $(r_{m-p+1}, \dots, r_{m-p+n_{L+1}})$ and $C^{(1)}$;
if $(m - p + n_{L+1} + 1) \leq i \leq m$ and $1 \leq j \leq n$, **then** perform Ryser's
reconstruction algorithm on the row and column vectors:
 $(r_{m-p+n_{L+1}+1}, \dots, r_m)$ and $C^{(2)}$;
Step 3: for all $m - p + 1 \leq i \leq m$ and $1 \leq j \leq n$,
if $a'(i, j) = 1$ **then** $a'(i - pk, (j + k) \bmod n) = 1$ with $1 \leq i - pk \leq m - p$.

Proposition 2. *The matrix A' which is the output of the Algorithm 3 is $(p, 1)$ -periodical and it has row and column sums equal to (R', C') .*

We do not show the proof of this Proposition for brevity's sake.

By performing Algorithm 1, the reduction of Section 4.1, the reduction to 2-SAT problem, a linear-time algorithm for solving 2-SAT problem [3], and Algorithm 3, we obtain a $(p, 1)$ -periodical binary matrix A having row and column sums equal to (R, C) . Since each step can be performed in polynomial time, we have that:

Theorem 2. *The problem of reconstructing $(p, 1)$ -periodical binary matrices from their row and column sums can be solved in polynomial time.*

5 Conclusions

Our main purpose has been to introduce periodicity properties in terms relevant for Discrete Tomography. The periodicity is a natural constraint and it has not yet been studied in this field. The motivation of this study is in the attempt to tackle the ill-posedness of the reconstruction problem by limiting the class of possible solutions using appropriate prior information. This means that, we modelled a priori information in terms of a subclass of binary images to which the solution must belong.

By using the periodicity properties we reduce the class of possible solutions. For instance, we proved a uniqueness result for the class of binary matrices having period $(1, 1)$. We have shown a simple greedy algorithm for reconstructing this class of matrices from their row and column sums. This reconstruction problem becomes more difficult for the binary matrices having period $(p, 1)$ or $(1, q)$. We have described a polynomial-time algorithm for solving this problem which use a reduction to 2-Satisfiability problem. We stress the fact that an interesting property of this approach is that it can be used for reconstructing parallelogram polyominoes lying a cylinder from row and column sums.

The future challenges concern the reconstruction of binary matrices with a generical period (p, q) . We wish to point out that this paper is only an initial approach to the problem of reconstructing binary matrices having periodicity properties from a small number of discrete X-rays. Lot of work should be done to understand such environment: we only challenge the reconstruction problem from two X-rays in some special cases, but MANY consistency, reconstruction and uniqueness problems can be reformulated imposing periodical constraints.
